Metalinguistic Abstraction

Metalinguistic abstraction: Establishing new technical languages (such as programming languages)

$$f(x) = x^2 - 2x + 1$$

$$\lambda f.(\lambda x.f(x \ x))(\lambda x.f(x \ x))$$

In computer science, languages can be implemented:

- An interpreter for a programming language is a function that, when applied to an expression of the language, performs the actions required to evaluate that expression.
- The *semantics* and *syntax* of a language must be specified precisely in order to build an interpreter.

Syntax and Semantics of Calculator

Expression types:

- A call expression is a Scheme list
- A primitive expression is an operator symbol or number

Operators:

- The + operator returns the sum of its arguments
- The operator returns either
 - $\mbox{\ }^{\square}$ the additive inverse of a single argument, or
 - the sum of subsequent arguments subtracted from the first
- ${}^{\circ}$ The * operator returns the product of its arguments
- The / operator returns the real-valued quotient of a dividend and divisor (i.e., a numerator and denominator)

Programming Languages

Computers have software written in many different languages.

Machine languages: statements can be interpreted by hardware

- All data are represented as sequences of bits
- All statements are primitive instructions

High-level languages: hide concerns about those details

- Primitive data types beyond just bits
- Statements/expressions can be non-primitive (e.g., calls)
- Evaluation process is defined in software, not hardware

High-level languages are built on top of low-level languages

Machine language

С

Python

The Scheme-Syntax Calculator Language

A subset of Scheme that includes:

- Number primitives
- Built-in arithmetic operators: +, -, *, /
- Call expressions

Expression Trees

A basic interpreter has two parts: a parser and an evaluator

```
scalc.py
               scheme_reader.py
   lines
                                     expression
                                                              Evaluator
                                                                                  value
                   Parser
 '(+ 2 2)'
                            Pair('+', Pair(2, Pair(2, nil)))
'(* (+ 1'
                             Pair('*', Pair(Pair('+', ...)))
       (- 23)'
                                        printed as
       (* 4 5.6))'
                              (* (+ 1 (- 23) (* 4 5.6)) 10)
   10)'
 Lines forming
                             A number or a Pair with an operator as its first element
 a Scheme
expression
                                                                                A number
```

Syntactic Analysis

Syntactic analysis identifies the hierarchical structure of an expression, which may be nested.

Each call to scheme_read consumes the input tokens for exactly one expression.

```
(', '+', 1, '(', '-', 23, ')', '(', '*', 4, 5.6, ')', ')'
```

Base case: symbols and numbers

Recursive call: scheme_read sub-expressions and combine them

Demo (http://inst.eecs.berkeley.edu/~cs61a/fa12/projects/scalc/scheme_reader.py.html)

Evaluation

Evaluation discovers the form of an expression and then executes a corresponding evaluation rule.

- Primitive expressions are evaluated directly.
- Call expressions are evaluated recursively:
 - Evaluate each operand expression
 - Collect their values as a list of arguments
 - Apply the named operator to the argument list

Demo

Applying Operators

Calculator has a fixed set of operators that we can enumerate

Demo

Read-Eval-Print Loop

The user interface to many programming languages is an interactive loop, which

- Reads an expression from the user,
- · Parses the input to build an expression tree,
- Evaluates the expression tree,
- Prints the resulting value of the expression.

Demo

Raising Application Errors

The sub and div operators have restrictions on argument number.

Raising exceptions in apply can identify such issues:

```
def calc_apply(operator, args):
    """Apply the named operator to a list of args."""
    ...
    if operator == '-':
        if len(args) == 0:
            raise TypeError(operator + ' requires at least 1 argument')
    ...
    if operator == '/':
        if len(args) != 2:
            raise TypeError(operator + ' requires exactly 2 arguments')
    ...
```

Handling Errors

The REPL handles errors by printing informative messages for the user, rather than crashing. $\label{eq:control} % \begin{array}{c} \left(\left(\frac{1}{2}\right) + \frac{1}{2} \left(\frac{1}{2}\right)$

Demo

A well-designed REPL should not crash on any input!
