Fall 2013

Version Control and Homework Submission

1 Introduction

Your work in this course generally consists of producing numerous on-line documents: programs, homework answers, test files, and so forth. As a result, there are various recurring issues to address:

- How can you protect yourself against accidents (losing a file or laptop, for example)?

- What happens if you realize that changes you've made to your solution don't work, but no longer have the previous version to go back to?

- How can you review your recent changes?

- If you work with a partner on an assignment, how do you coordinate changes that you make?

- If you work at various sites (e.g., at home and in a computer lab), how do you keep copies of an assignment on the two systems synchronized?

- How do you hand in your assignment?

There are real-world analogues of all these questions, and there is also a common tool for answering them: a *version-control system.*

A version-control system (also *source-code control system* or *revision-control system*) is a utility for keeping around multiple versions of files that are undergoing development. Basically, it maintains copies of as many old and current versions of the files as desired, allowing its users to retrieve old versions (for example, to "back out" of some change they come to regret), to compare versions of a file, to merge changes from independently changing versions of a file, to attach additional information (change logs, for example) to each version, and to define symbolic labels for versions to facilitate later reference. No serious professional programmer should work without version control of some kind.

SUBVERSION, which we'll be using this semester, is an open-source version-control system that enjoys considerable use. The basic idea is simple: SUBVERSION maintains *repositories,* each of which is a set of *versions* (plus a little global data). A version is simply a snapshot of the contents of an entire directory structure—a hierarchical collection of directories (or "folders" in the Mac and PC worlds) that contain files and other directories. A repository's administrator (in this class, that's the staff), can control which parts of the repository any given person or group has access to. SUBVERSION is an example of a *client/server* system. That is, running it requires two programs, one of which (the server) accesses the repository and responds to requests from the other program (the client), which is what you run. The client and server need not run on the same machine, allowing remote access to the repository. We have one server program, which the staff will look after, and several alternatives

for the client program, depending on how you are working. In this document, we'll describe the standard command-line client (called `svn`), which you run in a shell.

The staff will maintain a Subversion repository containing subdirectories for each of you on the instructional machines. The Subversion server program manipulates this repository and runs on one of the instructional machines. You will be able to run the Subversion client program (`svn`) either from your class account or remotely from any machine where `svn` is installed.

Your subdirectory will contain subdirectories of its own corresponding to the course assignments. At any given time, you may have *checked out* a copy of all or part of these assignment directories into one of your own directories (known as a *working directory* or *working copy*.) You can make whatever changes you want (without having any effect on the repository) and then create (*commit* or *check in*) a new version containing modifications, additions, or deletions you've made in your working directory.

If you are working in a team, another member might check out a completely independent copy of the same version you are working on, make modifications, and commit those. You may both, from time to time, *update* your working directory to contain the latest committed files, including changes from other team members. Should several of you have changed a particular file—you in a committed revision, let us say, and others in their working copies—then the others can update their working copies with your changes, *merging* in any of your changes to files you've both modified. After these team members then commit the current state of their working directories, all changes they've made will be available to you on request. If you attempt to commit a file that someone else has modified and committed, then Subversion will require you to update your file (merging these committed changes into it) before it will allow you to commit.

Should you mess something up, all the versions you created up to that point still exist unchanged in the repository. You can simply fall back to a previous version entirely, or replace selected files from a previous version. Of course, to make use of this facility, you must check your work in frequently.

Even though the abstraction that Subversion presents is that of numbered snapshots of entire directory trees full of files, its representation is far more efficient. It actually stores *differences* between versions, so that storing a new version that is little changed from a previous one adds little data to the repository. In particular, the representation makes it particularly fast and cheap to create a new version that contains an additional copy of an entire subdirectory (but in a different place and with a different name). No matter how big the subdirectory is, the repository contains only the information of what subdirectory in what version it was copied from. You can use these cheap copies to get the effect of *branching* a project, and of *tagging* (naming) specific versions. These copies have other uses as well. In particular, they allow you to import a set of skeleton files for an assignment without significantly increasing the size of the repository.

Subversion is a reasonably complex system with many features, and past experience has shown me that students have an uncanny ability to mess up their working copies in mysterious ways. Therefore, I have implemented a command, `hw`, which "cans" a set of interactions of Subversion that covers most of what we need for this course. You are still free, if sufficiently motivated, to use Subversion directly (there are links to the full documentation on the course web pages), but we won't require it.

2   Basic Actions

Our version-control software manipulates two things:

A repository, which is maintained outside your directories and contains copies of all versions of all your assignments that you have *committed*. Each of these committed versions has a *revision number* in the repository. Revision numbers of your directories are increasing, but will not, in

general, be consecutive, since the number reflects all commits of all assignments made by all students.

Working directories, which reside in your personal file space (on one or more machines) and contain copies of assignments from the repository, together with local changes you have made to these assignments.

2.1   Committing

You do all your work on your local copies—your working directories. As you do so, they will diverge from the contents of the repositories. Periodically (which we suggest you interpret as "often"), you reconcile your working directory with its corresponding repository directory by copying changes to the working directory to the repository, thus creating a new version of an assignment. We call this copying process *committing* (or *checking in*) your changes.

2.2   Updating

Sometimes, you will want to have several working copies of a single assignment. For example, you may want to do most of your work on your laptop computer, but occasionally work on an assignment using the instructional servers[1]. When you do that, you have to be sure that your working directory reflects any changes you made while working on the other system. To this end, you must be careful to commit changes one copy when you are finished working on that copy, and must then *update* the other working directory before you begin work there. Updating a directory copies changes from the repository to the working copy[2].

2.3   Checking out copies

When the repository already contains versions of an assignment, you can start a new working directory by copying the latest version to a directory. This process is called *checking out* the assignment from the repository.

2.4   Submitting (tagging)

When your repository contains a version of an assignment that you think suitable for handing in, you submit it by creating a copy of the entire assignment in a particular repository directory, recognized by our submission software. In effect, you create a repository directory that names a particular version of a particular assignment. In version-control lingo, we call such a directory copy a *tag*. Once submitted, the contents of the tag don't change. Any changes you commit to your working directory have no effect on your submissions (but you can always create a new submission of these new contents). The system maintains copies of all your submissions, as well as all committed versions of your assignment.

2.5   Logs

Whenever you commit a version of an assignment, you will be asked to provide commentary on that version, which becomes the *log entry* for that version. The log is part of the *metadata* of the repository

---

[1]Using `ssh` to connect to the instructional machines from your laptop counts as "using the instructional servers" for this purpose.

[2]If you have modified one working copy after committing to the repository a different working copy, the updating process is clever enough to *merge* the changes rather than simply overwriting the working copy that you are updating. However, this is an imperfect process (especially when the changes overlap) and it is much safer to make sure that you always commit when you finish working on one directory and always update when you start working on another.

contents—the data about the data. In the real world, logs are extremely useful. They allow changes to be attached to explanations of the changes, including which bug reports are addressed by these changes. The version-control software can then produce a report showing the entire change history for a project (i.e., a real-world "assignment") or for an individual file, complete with dates and authors. Figure1 shows an example taken from the open-source GDB debugger project. You probably won't have anything so elaborate, but you should try to say something useful to remind yourself of which committed versions to consider when trying to resurrect the previous contents of a file.

2.6 URLs

If you have installed `hw` on your personal computer and are working there instead of on the instructional servers, you will need to tell `hw` where to find the instructional repository. If necessary, `hw` will ask for the URL (Uniform Resource Locator) or your instructional login, and save it for future use. If you are using SUBVERSION "bare" or through Eclipse, you will need to know the full URL, which is

$$\texttt{svn+ssh://cs61b-ta@torus.cs.berkeley.edu/}LOGIN$$

where $LOGIN$ is your instructional account name (`cs61b-`xx).

Each of your assignments will reside in a repository directory at URL

$$REPOS\texttt{/trunk/}ASSIGNMENT$$

where $RESPOS$ is the URL for your respository, described above. Each submission of an assignment will reside at URL

$$REPOS\texttt{/tags/}ASSIGNMENT\text{-}SEQ$$

where SEQ is a sequence number (you can have multiple submissions of the same assignment; the sequence numbers distinguish them.) Finally, the templates for assignments reside at

$$\texttt{svn+ssh://cs61b-ta@torus.cs.berkeley.edu/staff/}ASSIGNMENT$$

Again, you don't need this information if using SUBVERSION through the `hw` command.

3 The 'hw' Command

On the instructional machines, we've provided the command `hw`, which performs a number of functions. The general form of the command is

```
$ hw subcommand arguments
```

where *subcommand* identifies the particular function to be performed. You may abbreviate *subcommand* with any subsequence that starts with the same letter and uniquely identifies the command. For example, you can substitute "`hw ch hw1`" or "`hw ck hw1`" for "`hw checkout hw1`."

For those of you running MacOS or Linux, you can download `hw` from the course web pages. It requires that you have Python 3, SUBVERSION, and `ssh` installed on your system. At the moment, we don't support a Windows version. If you use `hw` from home, you should be particularly careful to commit changes frequently (see §3.4) and—if you move between working from your home computer and working on the instructional machines—to update your working copy (see §3.3) whenever you change from one to the other. This is a better way of transferring work between systems than using `scp`, `rsync`, or PuTTy.

```
commit 5979b98b41bdda7c396caa1ccd90c07bc416d70e
Author: Joel Brobecker <brobecker@adacore.com>
Date:   Sat Jun 9 12:24:29 2012 -0400

    Change detach_breakpoints to take a ptid instead of a pid

    Before this change, detach_breakpoints would take a pid, and then
    set inferior_ptid to a ptid that it constructs using pid_to_ptid (pid).
    Unfortunately, this ptid is not necessarily valid.  Consider for
    instance the case of ia64-hpux, where ttrace refuses a register-read
    operation if the LWP is not provided.

    This problems shows up when GDB is trying to handle fork events.
    Assuming GDB is configured to follow the parent, GDB will try to
    detach from the child. But before doing so, it needs to remove
    all breakpoints inside that child.  On ia64, this involves reading
    inferior (the child's) memory. And on ia64-hpux, reading memory
    requires us to read the bsp and bspstore registers, in order to
    determine where that memory is relative to the value of those
    registers, and thus to determine which ttrace operation to use in
    order to fetch that memory (see ia64_hpux_xfer_memory).

    This patch therefore changes detach_breakpoints to take a ptid instead
    of a pid, and then updates all callers.

    One of the consequences of this patch is that it trips an assert
    on GNU/Linux targets.  But this assert appears to have not actual
    purpose, and is thus removed.

    gdb/ChangeLog:

            * breakpoint.h (detach_breakpoints): pid parameter is now a ptid.
            * breakpoint.c (detach_breakpoints): Change pid parameter into
            a ptid.  Adjust code accordingly.
            * infrun.c (handle_inferior_event): Delete variable child_pid.
            Update call to detach_breakpoints to pass the child ptid for
            fork events.
            * linux-nat.c (linux_nat_iterate_watchpoint_lwps): Remove
            assert that inferior_ptid's lwp is zero.
            (linux_handle_extended_wait): Update call to detach_breakpoints.

    For L607-025.

Notes:
    Submitted: http://www.sourceware.org/ml/gdb-patches/2012-06/msg00486.html
```

Figure 1: An example of a log message for a commit. This is taken from a local development branch of the GDB (GNU Debugger) project. The version-control system used here is `git`, which is also used for Linux development. The last four lines give tracking information that refers to an internal bug-tracking system and to the public GDB repository. This example is considerably more elaborate than anything you'll want to write!

3.1 Starting an assignment: working directories

The `hw` command assumes that your working directories have the same names as the repository subdirectories they are copied from, which will themselves all have the names of assignments (e.g., 'hw1' or 'proj1')[3].

For each assignment, we provide a template containing skeletons of files you will eventually submit (although you may also have to add others). To start work on an assignment (let's say `hw1`), place yourself in the directory you'll use to hold your work (which could be your home directory), and use the command:

```
$ hw init hw1
```

This does several things:

1. Creates a new entry in your repository called `hw1`, and containing our initial template for `hw1`.

2. Creates a new working (sub)directory called `hw1`.

3. Copies the files from your `hw1` repository entry into this new working directory.

You only initialize an assignment once (`hw` won't let you do it again). After that, you either work on the working `hw1` directory created in step 2, or you can create another working copy of the repository entry with the `hw checkout` command (§3.4).

3.2 Checking out an assignment

Once you have initialized an assignment, you can use the working directory that `hw init` creates. All committed copies of work done to that directory are retained in the class repository, regardless of what happens to your working directory. However, if you need to produce a new working directory for an assignment (say `hw1` to continue our running example) (perhaps on a different machine), you can do so with the command:

```
$ hw checkout hw1
```

Old versions. You can use the `hw checkout` command to fetch any previous version of an assignment that you have committed. First, use `hw log` to find the revision number of the version you want (§3.10). Then fetch the desired version (let's say revision number 42 of assignment `hw1`) with the command

```
$ hw checkout hw1-r42
```

This creates a new directory named `hw1-r42` containing the desired version[4]. To prevent accidents, this new directory is *not* a working directory (that is, it is missing the hidden information that links it back to the repository). However, by copying selectively from `hw1-r42` into a working directory for `hw1`, you can roll back the clock on any desired file.

---

[3]In fact, once a working directory is created, its name no longer matters (the system maintains information about which assignment it came from inside the working directory itself). You can change the name of the working directory if desired (using the Unix `mv` command, for example). We suggest, however, that you avoid this if possible.

[4]Revision numbers apply to the class repository as a whole; they increase whenever *anybody* commits to the repository, so revision 42 might not be a revision at which you committed `hw1`. If so, you will instead get whatever version of `hw1` you last committed before revision 42 of the repository.

Retrieving submissions. The `hw checkout` command will also fetch assignments you have submitted (see §3.5). For example, to get a copy of submission number 2 of `hw1`, type

```
$ hw checkout hw1-2
```

You can use `hw submissions` to list all your submissions (see §3.7). Again, the resulting directory will not be a working directory, but you can copy its contents into a working directory if desired.

3.3 Updating

To make sure that a working directory, say `hw1`, has the same contents as the latest repository entry, use the command

```
$ hw update hw1
```

or, if `hw1` is already your current directory, just

```
$ hw update
```

This provides a convenient way to transfer work from home to the instructional machines or vice-versa: be sure to commit the work when finished working on one of the directories, and then run "`hw update`" in the other.

The command will complain if something goes wrong, such as

- Attempting to update a directory that is not a working copy.

- Attempting to update a non-existent directory.

- Updating a directory to which you have made conflicting changes before updating from the repository. This happens, for example, if you commit changes on your laptop, then change some of your files on the instructional machines in places that overlap the changes you just committed, and only then remember to update the working copy on the instructional machines.

3.4 Committing

At frequent intervals (and certainly when you pause to go do something else), you should send a new version—a snapshot—of your working directory to the repository. It *never* hurts to do this. The command

```
$ hw commit hw1
```

commits the contents of the working directory named `hw1`. If you are already in a working directory for an assignment, simply use

```
$ hw commit
```

The system will ask for a log message, by opening up an editor session. Type whatever you want and exit from the editor.

Plain SUBVERSION commits only files that you've told it about, and it gets upset if you have deleted a file without telling it that you've done so. The `hw` command will prompt you about any such files. If you have created a new file or directory in your working directory that is not currently in the respository (say `NewFile.java`), `hw commit` will give you a message such as

```
NewFile.java is untracked.  Add it? [y]
```

Generally, you'll want to answer "y" or "yes" (or simply return) to cause `NewFile.java` to get added to the repository. If you have deleted a file (say `BadFile.java`), `hw commit` will ask

```
    BadFile.java has been deleted.  Remove from the repository, too? [y]
```

Responding 'y' will remove `BadFile.java` from the next committed version in the repository. However, since the repository contains all committed versions of your working directory, you will still be able to recover old versions of `BadFile.java` (see).

After asking about these files, `hw  commit` will perform a `hw update` command to make sure that you don't undo changes to the repository that were made previously. Finally, it will commit your changes (creating a new version of the assignment in the repository).

There are certain files that `hw` does not track by default. The main ones are Java `.class` and `.jar` files, files that end in '~' or '#', and files containing Eclipse metadata.

Again, the command will complain if something goes wrong. It is best to consult the staff when this happens, because it means that you have *not* saved you recent work and simply pushing on will just confuse things still further.

3.5 Submitting

To submit the assignment in a given directory (say `hw1`), use the command

```
    $ hw submit hw1
```

or, if you are already in your `hw1` working directory,

```
    $ hw submit
```

The system will first commit the current directory, if necessary (see §3.4). It will tell you the name it chose for the submission, as in:

```
    $ hw submit
    Submitting hw1-3...
    Submission complete.
```

As usual, if you don't see messages like this, something went wrong; don't assume the submission was successful.

3.6 Reverting changes

Once a file is committed for the first time and is therefore in the repository, it is said to be *tracked*. After you change a tracked file in a working directory (including by deletion), but before you next commit the directory, you can restore that file to its previous contents (that is, its contents as of the previous commit or update). For example, if you accidentally delete or otherwise mutilate `Solver.java`, you can get it back with

```
    hw revert Solver.java
```

This won't work for files you have just created and not yet committed, since the system has no prior copy of them. Likewise, it will not restore the contents of a file from a previous revision—from before the last `commit`. To do that, use the `hw checkout` to fetch the previous revision and then copy the desired file from there into the working directory.

3.7   Listing assignments and submissions

To see a list of all your submissions of a given assignment (say `hw1`), use

```
$ hw submissions hw1
```

This will tell you the submission sequence numbers, dates, and times of all submissions of the assignment The command

```
$ hw submissions
```

will do the same for all assignments you've submitted.

To list all the assignments you've worked on or started (and therefore committed to the repository, but perhaps not submitted), use the command

```
$ hw assignments
```

which lists the assignments and the last time you committed each.

3.8   Status of a working directory

To see which files you've changed, added, or deleted relative to the last `hw commit` for our `hw1` assignment, use the command

```
$ hw status hw1
```

or just

```
$ hw status
```

if you are already in the working directory. This will give a list of files and the status of each. For example:

```
$ hw status
Files and directories that are not in the repository yet,
  but will be added by 'hw commit':
    NewFile.java
    tests/NewTest.data

Files you have modified, but not committed:
    Main.java

Files and directories you have deleted, but not committed:
    Optional.java
```

When you see files listed by `hw status` like this, it generally suggests that you have material to commit. On the other hand,

```
$ hw status
No changes since last commit
```

means that nothing remains to be committed.

The related commands

```
$ svn list hw1
$ svn list
```

produce the same results as `svn status`, but in addition produce a list of other tracked files that are unchanged.

```
$ hw diff

```

Figure 2: Example of `hw diff`.

3.9   Listing differences

The `hw diff` command allows you to see the changes you've made to a working directory since committing it or checking it out, but have not yet committed. Without an additional argument, it lists differences for the current directory. With an argument, it lists differences in the named directory or file. Figure 2 shows an example of a command and resulting output. The output shows lines that you have added to the working file (indicated by a leading '+'), those that you have deleted (leading '-'), and those you have modified (which show up as a deletion of the old line and an addition of the new version). The listing also includes a few lines of context on either side of changes to help locate the change (also, the lines beginning '@@' indicate line numbers in the old and new versions.)

By supplying a revision number (see §3.10 for finding revision numbers), you can compare the working directory against a revision other than the last one in the repository. For example

```
$ hw diff 130
```

compares the working directory with whatever contents were committed for revision 130. The command

```
$ hw diff Main.java 130
```

does the same for the single file `Main.java`.

3.10 Listing log information

To get a listing of the commits you've made to the assignment in the current directory, use the command

```
hw log
```

which gives a listing something like this:

```
------------------------------------------------------------------------
r146 | cs61b-yu | 2012-09-07 16:20:30 -0700 (Fri, 07 Sep 2012) | 10 lines
Changed paths:
   M /cs61b-yu/trunk/hw1/Progs.java

Solve problem 3.

Changed paths:
   M /cs61b-yu/trunk/hw1/Progs.java
   M /cs61b-yu/trunk/hw1/HW1Test.java

Solve problems 1&2.
Add tests for same.

------------------------------------------------------------------------
r130 | cs61b-yu | 2012-09-06 16:10:50 -0700 (Thu, 06 Sep 2012) | 2 lines
Changed paths:
   A /cs61b-yu/trunk/hw1 (from /staff/hw1)

Start hw1.

------------------------------------------------------------------------
```

Each commit produces an entry giving the revision number, date, time, the files changed, and the log message.

To limit the number of log entries listed to the most recent N entries, use

```
hw log N
```

or to track entries mentioning a single file (say `Progs.java`), use

```
hw log Progs.java
```

or

```
hw log Progs.java N
```

for the latest N entries about `Progs.java`.

4   Summary of Basic Use

Let's look at the entire "life cycle" of assignment `hw1`. Let's assume that you group homework directories in a single directory called `hw`, which you have created with

```
$ mkdir ~/hw      # Make directory 'hw' in your home directory.
```

To start `hw1`, get a copy of its template:

```
$ cd ~/hw
$ hw init hw1     # Creates directory ~/hw/hw1
```

A typical basic work cycle then goes like this:

```
$ cd ~/hw/hw1
edit, test, debug
$ hw commit      # You'll be asked to supply a log message
edit, test, debug
$ hw commit
...
$ hw submit      # This also commits, if needed
```

If you work from home (and have installed the `hw` command), you can import work from school with

```
$ hw checkout hw1
```

This may ask you for the repository URL, which you can find by logging into your instructional account and typing

```
$ echo $MYREPOS
```

It will be something like

```
svn+ssh://cs61b-ta@torus.eecs.berkeley.edu/{\it YOURLOGIN}
```

The same commands should work from your home account as at school (that is, when you actually do your editing, compilation, and debugging using your own computer as opposed to using `ssh` to login in remotely to the instructional machines.) When switching from home to the instructional machines, be sure to run `hw commit` when done at home, and

```
$ cd ~/hw/hw1
$ hw update
```

before doing any editing on the instructional machines (likewise going in the other direction). This will transfer your work from one location to the other.

The `init`, `commit`, and `submit` commands are sufficient for creating and submitting homework on the instructional machines. For remote work, you may also need `checkout` and `update`. The other commands in §3 allow you to compare your current work with copies of it saved or submitted to the repository.

5   Using 'hw' at Home

The 'hw' command should work on Linux or MacOS systems. First, you'll need to have `ssh`, Subversion, and Python 3 installed on your system (use Google to find out how for your system). You can obtain `hw` with the command

> `$ scp -p` *YOUR_LOGIN*`@torus.cs.berkeley.edu:/home/ff/cs61b/bin/hw` *DIR*

where *DIR* is the directory where you want to store the command (a directory listed in `$PATH`.) When you run `hw` for the first time, it will ask for your instructional login or a URL, which you should provide (providing your login is easiest.)

In order for 'hw' to work, `ssh` must know about the SSH key that was issued with your CS61B account. This key is the file `~/.ssh/id_rsa` in your instructional account. Download that file into your own `~/.ssh` directory (probably with a different name, because you are like to already have a key of that name.) For example, you might use the command

> `$ scp` *YOUR_LOGIN*`@torus.cs.berkeley.edu:.ssh/id_rsa ~/.ssh/id_rsa_cs61b`

Assuming you do this, you should also add the line

> `IdentityFile ~/.ssh/id_rsa_cs61b`

to the file `~/.ssh/config`, creating that file if it does not already exist. Once you've done this, by the way, you should be able to use commands like `ssh`, `scp`, or `rsync` without having to supply a password.

6 Quick Reference

Here is a quick recap of the available commands. You can get the same information with `hw help`.

In what follows, optional arguments are denoted with square brackets (`[]`), and alternatives are separated by vertical bars (`|`). When a command takes an argument that can be a directory (denoted "<*dir*>") it refers to a working directory and, if defaulted, refers to the current directory.

Commands:

hw init <assignment> Create a fresh working directory named <assignment> containing the initial files (if any) for the assignment of that name. Commits the working directory to your repository, creating an entry for <assignment> (which must not have previously existed).

hw checkout <assignment> Create a fresh working directory named <assignment> containing a copy of the latest version of <assignment> from your repository.

hw checkout <assignment>-<number> Create a fresh directory named <assignment>-<number> containing a copy of the tag (submission) named <assignment>-<number> from the repository. This is NOT a working copy, and cannot be committed back to the repository.

hw checkout <assignment>-r<number> Create a fresh directory named <assignment>-r<number> containing a copy of previously committed revision <number> of <assignment> from the repository. To find revision numbers for past commits, use the 'hw log' command. The resulting directory is NOT a working copy, and cannot be committed back to the repository.

hw update [<dir>] Copies any changes in the repository copy of the assignment in <dir> into <dir>. Reports any conflicts (such as files in the working directory that have been changed in a way that differs from ho the repository version was changed).

hw revert <file> Reverts <file> to its state just after the last commit, checkout, or init. If <file> was modified or deleted, restores its previous contents.

hw commit [<dir>] Copies the contents of <dir> to the repository, thus creating a new version. First asks about any anomalies, such as files that have been added, deleted, or incompletely merged.

hw submit [<dir>] Submit the contents of <dir>, creating a "tag". First runs various checks that the submission is complete. The directory must be the top-level directory for an assignment.

hw status [<dir>] List the files in <dir> that differ from the contents of the repository, indicating which are modified, and which are not tracked (i.e., not in the repository in any version).

hw diff [<file> | <dir>] [<revision number>] Reports differences between contents of <file or dir> (default, current directory), and the last version of it that was checked out.

hw list [<dir>] List all files in <dir> indicating any that are modified, or are not tracked (i.e., not in the repository in any version). This is like 'status', but includes all files.

hw log [<dir>] [<lim>] List log entries for commits of <dir>, most recent first. If <lim> is specified, it is an integer indicating the maximum number of entries.

hw assignments Lists all the assignments you have worked on and committed to the repository, whether or not you've submitted them.

hw submissions [**<assignment>**] Lists all your submissions of <assignment> in the repository, or, if assignment is defaulted, all your submissions of all assignments.
